## Latent Constituents via Self-Attention

August 22, 2018

### 1 Introduction

### 2 Problem

We would like to learn a generative model over source sentences  $\mathbf{x} = \{x_0, x_1, \ldots\}$ , using a distribution over latent trees  $\mathbf{z}$ . We are primarily interested in the posterior distribution over trees given a sentence,  $p(\mathbf{z} \mid \mathbf{x})$ . The performance of the generative model is secondary since we would like to analyze the output of the unsupervised model for any linguistic regularities, and use the model as a testbed for linguistic hypotheses (of which I have none at the moment).

(Shen et al., 2018) Yin et al. (2018)

## 3 PRPN (Shen et al., 2018)

The Parsing-Reading-Predict Network (Shen et al., 2018) is an approach to unsupervised tree induction that uses a soft approximation to a latent variable to a degree of success. The paper is inspired by the following hypothesis: given a binary tree, a token at index t only requires information up to index  $l_t$  that satisfies either of the following conditions:

- (a) the token at  $l_t$  is the leftmost sibling of the token at t
- (b) or, if the token at t is a leftmost child,  $l_t$  points to its parent's left sibling's leftmost child.

Although the hypothesis itself is not tested in the implementation and serves only as inspiration, the model does see empirical success in the task of language modeling. The model is realized through the following insight: given a ranking of tokens  $\mathbf{x} = \{x_0, \dots, x_T\}$ , recursively splitting  $\mathbf{x}$  using the following procedure induces a binary tree where the first token to the left of token  $x_t$  that has higher rank, denoted  $x_{l_t}$ , also satisfies condition (a) or (b): given token i with the next highest rank, create a subtree  $(x_{< i}, (x_i, x_{> i}))$  and recursively perform this procedure until only terminal nodes remain.

[Example on board]

# 4 Alternative Explanation

#### 4.1 The Model

Let  $x_t$  be the current token,  $\mathbf{x}_{0:t-1}$  all previous tokens,  $z_t$  the prediction for the current score, and  $\tilde{\mathbf{z}}_{0:t-1} \in \mathbb{R}^{t-1}_+$  be all previous scores. The model takes the form a language model, where the distribution over the next token

$$p(x_t \mid \mathbf{x}_{0:t-1}, \tilde{\mathbf{z}}_{0:t-1}, z_t) = f([h_{l_t:t-1}, h_t])$$

is parameterized by either a linear projection or additional residual blocks applied to a concatenation of the output of modified LSTMN (LSTM Memory-Network)  $h_t$  and a convex combination of the previous LSTMN outputs (i.e. attention over  $h_{l_t:t-1}$ ). f is referred to as the Predict Network.

#### 4.1.1 LSTMN

The LSTMN, referred to as the Reading Network, is as follows: at each time step, the hidden and cell input are given by

$$\{\tilde{h}_t, \tilde{c}_t\} = \sum_{i=1}^{t-1} s_i^t \{h_i, c_i\},$$

a convex combination of the previous hidden and cell outputs. Then

$$h_t, c_t = \mathtt{LSTM}(\tilde{h}_t, \tilde{c}_t).$$

The attention is computed in the same way as detailed in section 4.1.2. The input to the LSTMN module is either the previous token or the output of a previous LSTMN layer.

#### 4.1.2 Attention

As all attention modules in the PRPN network use the same formulation of attention we will use  $y_t$  to refer to the input of the attention module,  $g_t(l_t)$  the gate coefficients which are a function of the RV left-most limit  $l_t$ ,  $m_t$  as the memories to attend over, and  $s_t$  as the attention coefficients. First the key is computed using a linear projection of the input  $k_t = W_k y_t$ . Then the intermediate scores are computed

$$\tilde{s}_t^i = \operatorname{softmax}\left(\frac{m_t^i k_t^T}{\sqrt{\delta_k}}\right),\,$$

where  $\delta_k$  is the dimension of the hidden state. Finally, the gate coefficients are normalized and used to prevent the attention from extending too far in the past.

$$s_t^i = \frac{g_t^i(l_t)}{\sum_j g_t^j(l_t)} \tilde{s}_t^i,$$

where the gate coefficients  $g_t(l_t)$  are detailed in section 4.1.3.

#### 4.1.3 Gating Self-attention

Recall that the gates  $g_t^i$  also indirectly induce tree structure (due to the previously stated insight that modulating self-attention using a ranking induces a binary tree). At every timestep for token  $x_t$ , Shen et al. (2018) define a latent variable  $l_t$  which corresponds to the index of the token satisfying either condition (a) or (b). We then would have

$$q_t^i(l_t) = \mathbf{1}(l_t < i < t)$$

where we allow the model at timestep t to only attend up to the token at leftmost limit  $l_t$ . We would then renormalize the attention accordingly. In order to calculate the gates  $g_t^i(l_t)$  we must model  $p(l_t \mid \mathbf{x}_{0:t})$  (Shen et al. (2018) use the posterior distribution in their notation). They propose to model

$$p(l_t = i \mid \mathbf{x}_{0:t-1}) = (1 - \alpha_i^t) \prod_{j=i+1}^{t-1} \alpha_j^t$$

using a stick-breaking process.

Why not categorical?

A Dirichlet Process is used instead of a categorical distribution since it encodes the bias that nearer words should receive more ???? wut?? Encodes bias that we should attend to nearer words since we have a multiplicative decrease in mass. But this has nothing to do with the parameterization. The stick-breaking process is a sequence of local decisions, whereas with a gibbs distribution the scores are predicted individually then globally normalized. This lines up with the ranking procedure, since the ranking procedure uses pairwise comparisons. Learning to rank through sorting??? But the parameterization of the sorting is global as well. Given that we have a global ranking, could we parameterize a categorical distribution that preserves the induced self-attention distributions?

Is this really a Dirichlet Process? In a  $DP(\alpha, H_0)$  we have  $\pi \sim GEM(\alpha)$ , where  $b_i \sim Beta(1, \alpha)$  and  $\pi_i = (1 - b_i) \prod_{j=0}^{i-1} b_j$ . We then have  $\theta_i \sim H_0$  and  $G = \sum_i \pi_i \delta_{\theta_i} \sim DP(\alpha, H_0)$ .

Rather than resorting to approximate inference, they instead use the expected value of  $g_i^t$ 

$$\mathbb{E}\left[g_i^t(l_t)\right] = F_{l_t}(l_t \le i \mid \mathbf{x}_{0:t-1}) = \prod_{j=i+1}^{t-1} \alpha_j^t.$$

The  $\alpha_j^t = \sigma(d_t - d_j)$ , where  $\sigma$  is the hard sigmoid function. This is not stated in the paper (there are a couple off-by-one) errors, but it must be that  $g_{t-1}^t = 1$ . The  $d_j \in \mathbb{R}_+$  are given by a CNN over the token embeddings.

The network used to compute the gates is called the Parsing Network. When computing  $p(x_t \mid ...)$ , we cannot use the posterior score  $d_t$ , so an estimate is used based on the previous k words, where k is the kernel width of the convolution. However, afterwards Shen et al. (2018) use the posterior score for all  $d_i$  when i < t.

## 5 Comparison to CCM (Klein and Manning, 2002a)

(Klein and Manning, 2002b) (Golland et al., 2012; Huang et al., 2012)

- 6 Comparison to StructVae (Yin et al., 2018)
- 7 Related Work
- 8 Alternative Latent Ranking Model

#### 8.1 Generative Model

PRPN (Shen et al., 2018) choose to view  $l_t$  as a latent variable. There are at least a few other choices:

- Model the scores  $d_t \sim \mathcal{N}(\mu_t, \sigma_t)$  or  $d_t \sim \text{Gamma}$  and use the Plackett-Luce ranking distribution.
- Model the comparisons  $p(d_t < d_i)$  as order statistics of Gammas.
- Model the permutation matrix  $Z \sim \mathcal{B}_n$ .
- Model  $l_t \sim \text{Cat}$ .

Parameterize with  $d_t \sim \mathcal{N}(\mu_t, \sigma_t)$ . Reparameterize comparisons with gumbel softmax? Leave all self attentions as is?

- $\bullet$  p(z)
- $\bullet$  p(x|z)

# 9 Training and Inference

for next time, convince Sasha of why this is interesting. Also go over stick breaking process.
